# ABSTRACT

The FFLAS project has established that exact matrix multiplication over finite fields can be performed at the speed of the highly optimized numerical BLAS routines. Since many algorithms have been reduced to use matrix multiplication in order to be able to prove an optimal theoretical complexity, this paper shows that those optimal complexity algorithms, such as LSP factorization, rank determinant and inverse computation can also be the most efficient.

# 1. INTRODUCTION

Exact matrix multiplication over finite fields can now be performed at the speed of the highly optimized numerical BLAS routines. This has been established by the FFLAS project [8]. Moreover, since finite field computations e.g. do not suffer from numerical stability, this project showed also an easy effectiveness of the algorithms with even better arithmetic complexity (such as Winograd's variant of Strassen's fast matrix multiplication) [18].

Copyright 2004 ACM 1-58113-827-X/04/0007 ...\$5.00.

Now for the applications. Many algorithms have been designed to use matrix multiplication in order to be able to prove an optimal theoretical complexity. In practice those algorithms were only seldom used. This is the case e.g. in many linear algebra problems such as determinant, rank, inverse, system solution or minimal and characteristic polynomial. Over finite fields or over the integers those finite field linear algebra routines are used to solve many different problems. Among them are integer polynomial factorization, Gröbner basis computation, integer system solving, large integer factorization, discrete logarithms, error correcting codes, etc. Even sparse or polynomial linear algebra needs some very efficient dense subroutines [12, 10]. We believe that with our kernel, each one of those optimal complexity algorithms can also be the most efficient.

The goal of this paper is to show the actual effectiveness of this belief for the factorization of any shape and any rank matrices. The application of this factorization to determinant, rank, and inverse is presented as well.

Some of the ideas from FFLAS, in particular the fast matrix multiplication algorithm for small prime fields, are now incorporated into the Maple computer algebra system since its version 8. Therefore an effort towards effective reduction has been made within Maple by A. Storjohann[4]. Effective reduction for minimal and characteristic polynomial were sketched in [20] and A. Steel has reported on similar efforts within his implementation of some Magma routimes. We provide a full C++ package available directly<sup>1</sup> or through  $LinBox^{2}[7]$ . Extending the work undertaken by the authors et al. [18, 8, 3, 11], this paper focuses on matrix factorization, namely the exact equivalent of the LU factorization. Indeed, unlike numerical matrices, exact matrices are very often singular, even more so if the matrix is not square ! Consequently, Ibarra, Moran and Hui have developed generalizations of the LU factorization, namely the LSP and LQUP factorizations [16]. In section 4 we deal with the implementation of those two routines as well as memory optimized (an in-place and a cyclic block) versions using the fast matrix multiplication kernel. Those implementations require the resolution of triangular systems with matrix right or left hand side. In section 3 the triangular system solver (Trsm routine using BLAS terminology) is therefore studied. Then, in section 5, we propose different

uses of the factorization routine to solve other classical linear algebra problems. In particular, speed ratios are presented and reflects the optimal behavior of our routines.

#### **BASE FIELDS** 2.

The algorithms we present in this paper are written generically with regards to the field over which they operate, as long as they provide some conversion functions from a field element to a floating point representation and backwards. As demonstrated in [8] this is easily done for prime fields and also for other finite fields, via a q-adic transformation. The chosen interface is that of the LINBOX fields [22, §5.3]. In the following, the prime field with characteristic p will be denoted by  $\mathbb{Z}_p$ .

For our experiments we use some classical representations, e.g. modular prime fields, primitive roots Galois fields, Montgomery reduction, etc. implemented in different libraries, as in [8, 6]. Still and all, when no special implementation is required and when the prime field is small enough, one could rather use what we call a Modular<double> field representation. Indeed, the use of the BLAS imposes conversions between the field element representations and a corresponding floating point representation. Hence a lot of time consuming conversions can be avoided whenever the field element representation is already a floating point number. This is the case for the LINBOX prime field Modular<double>, where the exact representation of an element is stored within the mantissa of a double precision floating point number. Of course all the arithmetic operations remain exact as they are always performed modulo a prime number. In this paper, we only focus on two representations. The first one is Modular<double> and the second one is that of the Givaro library<sup>3</sup> which uses machine integer remaindering. This classical representation will be denoted by Givaro-ZpZ.

#### TRIANGULAR SYSTEM SOLVING 3. WITH MATRIX HAND SIDE

In this section we discuss the implementation of solvers for triangular systems with matrix right hand side (or equivalently left hand side). This is also the simultaneous resolution of n triangular systems. Without loss of generality for the triangularization, we here consider only the case where the row dimension, m, of the triangular system is less than or equal to the column dimension. n. The resolution of such systems is a classical problem of linear algebra. It is e.g. one of the main operation in block Gaussian elimination. For solving triangular systems over finite fields, the block algorithm reduces to matrix multiplication and achieves the best known arithmetic complexity. Therefore, from now on we will denote by  $\omega$  the exponent of square matrix multiplication (e.g. from 3 for classical, to 2.375477 for Coppersmith-Winograd). Moreover, we can bound the arithmetical cost of a  $m \times k$  by  $k \times n$ rectangular matrix multiplication (denoted by R(m, k, n)) as follows:  $R(m,k,n) \leq C_{\omega} \min(m,k,n)^{\omega-2} \max(mk,mn,kn)$ [15, (2.5)]. In the following subsections, we present the block recursive algorithm and two optimized implementation variants.

#### Scheme of the block recursive algorithm 3.1

The classical idea is to use the divide and conquer approach. Here, we consider the upper left triangular case without loss of generality, since the any combination of upper/lower and left/right triangular cases are similar: if Uis upper triangular, L is lower triangular and B is rectangular, we call ULeft-Trsm the resolution of UX = B, LLeft-Trsm that of LX = B, URight-Trsm that of XU = Band LRight-Trsm that of XL = B.

**Algorithm** ULeft-Trsm(A, B)**Input:**  $A \in \mathbb{Z}_p^{m \times m}, B \in \mathbb{Z}_p^{m \times n}.$ **Output:**  $X \in \mathbb{Z}_p^{m \times n}$  such that AX = B. Scheme  $\mathbf{if} \ \mathbf{m}{=}1 \ \mathbf{then}$ 

 $X := A_{1,1}^{-1} \times B.$ else (splitting matrices into  $\lfloor \frac{m}{2} \rfloor$  and  $\lceil \frac{m}{2} \rceil$  blocks)

$$\overbrace{\begin{bmatrix} A_1 & A_2 \\ A_3 \end{bmatrix}}^{A} \overbrace{\begin{bmatrix} X_1 \\ X_2 \end{bmatrix}}^{X_1} = \overbrace{\begin{bmatrix} B_1 \\ B_2 \end{bmatrix}}^{B}$$
$$X_2 := \texttt{ULeft-Trsm}(A_3, B_2).$$
$$B_1 := B_1 - A_2 X_2.$$
$$X_1 := \texttt{ULeft-Trsm}(A_1, B_1).$$

return X.

LEMMA 3.1. Algorithm ULeft-Trsm is correct and its theoretical cost is bounded by  $\frac{C_{\omega}}{2(2^{\omega-2}-1)}nm^{\omega-1}$  arithmetic operations in  $\mathbb{Z}_p$  for  $m \leq n$ .

PROOF. The correctness of algorithm ULeft-Trsm can be proven by induction on the row dimension of the system. For this, one only has to note that

$$X = \begin{bmatrix} X_1 \\ X_2 \end{bmatrix} \text{ is solution} \Longleftrightarrow \begin{cases} A_3 X_2 = B_2 \\ A_1 X_1 + A_2 X_2 = B_1 \end{cases}$$

Let C(m, n) be the cost of algorithm ULeft-Trsm where m is the dimension of A and n the column dimension of B. It follows from the algorithm that  $C(m,n) = 2C(\frac{m}{2},n) +$  $R(\frac{m}{2}, \frac{m}{2}, n)$ . By counting each operation at one recursive step we have:

$$C(m,n) = \sum_{i=1}^{\log m} 2^{i-1} R(\frac{m}{2^i}, \frac{m}{2^i}, n)$$

Now, since  $m \leq n$ , we get  $\forall i \ R(\frac{m}{2^i}, \frac{m}{2^i}, n) = C_{\omega}\left(\frac{m}{2^i}\right)^{\omega-1} n$ and therefore:

$$C(m,n) = \frac{C_{\omega}nm^{\omega-1}}{2}\sum_{i=1}^{\log m} \left(\frac{1}{2^i}\right)^{\omega-2}$$

which gives the  $O(nm^{\omega-1})$  bound of the lemma.

# 3.2 Implementation using the BLAS "dtrsm"

Matrix multiplication speed over finite fields was improved in [8, 18] by the use of the numerical BLAS<sup>4</sup> library: matrices were converted to floating point representations (where the linear algebra routines are fast) and converted back to a finite field representation afterwards. The computations remained exact as long as no overflow occurred. An implementation of ULeft-Trsm can use the same techniques.

 $<sup>^3</sup>$ www-id.imag.fr/Logiciels/givaro

<sup>&</sup>lt;sup>4</sup>www.netlib.org/blas

Indeed, as soon as no overflow occurs one can replace the recursive call to ULeft-Trsm by the numerical BLAS *dtrsm* routine. But one can remark that approximate divisions can occur. So we need to ensure both that only exact divisions are performed and that no overflow appears. Not only one has to be careful for the result to remain within acceptable bounds, but, unlike matrix multiplication where data grows linearly, data involved in linear system grows exponentially as shown in the following.

The next two subsections first show how to deal with divisions, and then give an optimal theoretical bound on the coefficient growth and therefore an optimal threshold for the switch to the numerical call.

#### 3.2.1 Dealing with divisions

In algorithms like ULeft-Trsm, all divisions appear only within the last recursion's level. In the general case it cannot be predicted whether these divisions will be exact or not. However when the system is unitary (only 1's on the main diagonal) the division are of course exact and will even never be performed. Our idea is then to transform the initial system so that all the recursive calls to ULeft-Trsm are unitary. For a triangular system AX = B, it suffices to factor first the matrix A into A = UD, where U, D are respectively an upper unit triangular matrix and a diagonal matrix. Next the unitary system UY = B is solved by any ULeft-Trsm (even a numerical one), without any division. The initial solution is then recovered over the finite field via  $X = D^{-1}Y$ . This normalization leads to an additional cost of:

• *m* inversions over  $\mathbb{Z}_p$  for the computation of  $D^{-1}$ .

•  $(m-1)\frac{m}{2} + mn$  multiplications over  $\mathbb{Z}_p$  for the normalizations of U and X.

Nonetheless, in our case, we need to avoid divisions only during the numerical phase. cwTherefore, the normalization can take place only just before the numerical routine calls. Let  $\beta$  be the size of the system when we switch to a numerical computation. To compute the cost, we assume that  $m = 2^i\beta$ , where *i* is the number of recursive level of the algorithm ULeft-Trsm. The implementation can however handle any matrix size. Now, there are  $2^i$  normalizations with systems of size  $\beta$ . This leads to an additional cost of:

• m inversions over  $\mathbb{Z}_p$ .

•  $(\beta - 1)\frac{m}{2} + mn$  multiplications over  $\mathbb{Z}_p$ .

This allows us to save  $(\frac{1}{2} - \frac{1}{2^{i+1}})m^2$  multiplications over  $\mathbb{Z}_p$  from a whole normalization of the initial system. One iteration suffices to save  $\frac{1}{4}m^2$  multiplications and we can save up to  $\frac{1}{2}(m^2 - m)$  multiplications with log *m* iterations.

#### 3.2.2 A theoretical threshold

The use of the BLAS routine trsm is the resolution of the triangular system over the integers (stored as double for dtrsm or float for strsm). The restriction is the coefficient growth in the solution. Indeed, the  $k^{th}$  value in the solution vector is a linear combination of the (n - k) already computed next values. This implies a linear growth in the coefficient size of the solution, with respect to the system dimension. Now this resolution can only be performed if every element of the solution can be stored in the mantissa of the floating point representation (e.g. 53 bits for double). Therefore overflow control consists in finding the largest block dimension b, such that the result of the call to dtrsm

will remain exact.

We now propose a bound for the values of the solutions of such a system; this bound is optimal (in the sense that there exists a worst case matching the bound when  $n = 2^i b$ ). This enables the implementation of a cascading algorithm, starting recursively and taking advantage of the BLAS performances as soon as possible.

THEOREM 3.2. Let  $T \in \mathbb{Z}^{n \times n}$  be a unit diagonal upper triangular matrix, and  $b \in \mathbb{Z}^n$ , with  $|T| \leq p - 1$  and  $|b| \leq p - 1$ . Let  $X = (x_i)_{i \in [1..n]} \in \mathbb{Z}^n$  be the solution of T.X = bover the integers. Then,  $\forall k \in [0..n - 1]$ :

$$\begin{cases} (p-2)^k - p^k \le 2\frac{x_{n-k}}{p-1} \le p^k + (p-2)^k & \text{if } k \text{ is even} \\ -p^k - (p-2)^k \le 2\frac{x_{n-k}}{p-1} \le p^k - (p-2)^k & \text{if } k \text{ is odd} \end{cases}$$

The proof is presented in appendix A. The idea is to use an induction on k with the relation  $x_k = b_k - \sum_{i=k+1}^n T_{k,i} x_i$ . Two lower and an upper bounds for  $x_{n-k}$  are computed, depending whether k is even or odd.

PROOF. We denote by  $u_n = \frac{p-1}{2} [p^n - (p-2)^n]$  and  $v_n = \frac{p-1}{2} [p^n + (p-2)^n]$  the bounds of the theorem 3.2. Now  $\forall k \in [0..n-1] u_k \leq v_k \leq v_{n-1}$ . Therefore the theorem 3.2 gives  $\forall k \in [1..n] x_k \leq v_{n-1} \leq \frac{p-1}{2} [p^{n-1} + (p-2)^{n-1}]$ 

Let 
$$T = \begin{bmatrix} \ddots & \ddots & \ddots & \ddots & \ddots \\ 1 & p-1 & 0 & p-1 \\ & 1 & p-1 & 0 \\ & & 1 & p-1 & 0 \\ & & & 1 & p-1 \\ & & & & 1 \end{bmatrix}$$
,  $b = \begin{bmatrix} \vdots \\ 0 \\ p-1 \\ 0 \\ p-1 \end{bmatrix}$ 

Then the solution  $X = (x_i)_{i \in [1..n]} \in \mathbb{Z}^n$  of the system T.X = b satisfies  $\forall k \in [0..n-1] |x_{n-k}| = v_k$ 

Thus, for a given p, the dimension n of the system must satisfy

$$\frac{p-1}{2} \left[ p^{n-1} + (p-2)^{n-1} \right] < 2^m \tag{1}$$

where *m* is the size of the mantissa so that the resolution over the integers using the BLAS trsm routine is exact. For instance, with a 53 bits mantissa, this gives quite small matrices, namely at most  $55 \times 55$  for p = 2, at most  $4 \times 4$  for  $p \leq 9739$ , and at most p = 94906249 for  $2 \times 2$  matrices. Nevertheless, this technique is speed-worthy in most cases as shown in section 3.4.

### 3.3 Recursive with delayed modulus

In the previous section we noticed that BLAS routines within **Trsm** are used only for small systems. An alternative is to change the cascade: instead of calling the BLAS, one could switch to the classical iterative algorithm: Let  $A \in \mathbb{Z}_p^{m \times m}$  and  $B, X \in \mathbb{Z}_p^{m \times n}$  such that AX = B, then

$$\forall i, X_{i,*} = \frac{1}{A_{i,i}} (B_{i,*} - A_{i,[i+1..m]} X_{[i+1..m],*})$$
(2)

The idea is that the iterative algorithm computes only one row of the whole solution at a time. Therefore its threshold t is greater than the one of the BLAS routine, namely it requires only

$$t(p-1)^2 < 2^m (3)$$

Resultantly, an implementation of this iterative algorithm depends mainly on the matrix-vector product. The arithmetical cost of such an algorithm is now cubic in the size of the system, where blocking improved the theoretical complexity. Anyway, in practice fast matrix multiplication algorithms are not better than the classical one for such small matrices [8,  $\S 3.3.2$ ]. In section 3.4 we compare both hybrid implementations with different thresholds to the pure recursive one.

Now we focus on the dot product operation, base for matrix-vector product. We use the results of [6], extending those of [8, §3.1]. There several implementations of a dot product are proposed and compared on different architectures. According to [6], where many different implementations are compared (Zech log, Montgomery, float, ...), the best implementation is a combination of a conversion to floating point representation with delayed modulus (for big prime and vector size) and an overflow detection trick (for smaller prime and vector size).

The first idea is to specialize dot product in order to make several multiplications and additions before performing the division (which is then delayed). Indeed, one needs to perform a division only when the intermediate result might overflow. Now, if the available mantissa is of m bits and the modulo is p, divisions happen at worst every n multiplications where n satisfies condition (3). There the best compromise has to be chosen between speed of computation and available mantissa. A double floating point representation gives actually the best performances for most of the vector and prime sizes [6]. Moreover one can then perform the division "à la NTL" using a floating point precomputation of the inverse:  $a * b \mod p = a * b - |a * b * p^{-1}| * p$ .

For small primes, however, there is a faster method: the second idea is to use an integer representation and to let the overflow occur. Then one should detect this overflow and correct the result if needed. Indeed, suppose that we have added a product ab to the accumulated result t and that an overflow has occurred. The variable t now contains actually  $t-2^m$ . Well, the idea is just to precompute a correction  $CORR = 2^m \mod p$  and add this correction whenever an unsigned overflow has occurred. Now for a portable unsigned overflow detection, we use a trick of B. Hovinen [14]: since  $0 < ab < 2^m$ , an unsigned overflow has occurred if and only if t + ab < t. Of course, better performances are attained when several products are grouped (whenever possible) so that test and correction are also delayed [6]. Figure 1, shows the "quasi-optimal performances" obtained using both techniques on a Pentium 3 (P3): the constant curve is the very good behavior of a simple delayed division with a double floating point representation and "à la NTL" divisions. The step curve is a blocked version of the overflow and correction idea where a change of step reflects the need of an additional division. An optimal implementation would switch to one or the other representation depending on the size of the prime and on the architecture.

### 3.4 "Trsm" implementations behavior

As shown in section 3.1 the block recursive algorithm Trsm is based on matrix multiplications. This allows us to use the fast matrix multiplication routine of the FFLAS package [8].

Figure 1: Speed improvement of dot product by delayed division, on a P3, 993 MHz

This is an exact wrapping of the ATLAS library<sup>5</sup> used as a kernel to implement the **Trsm** variants. In the following we denote by "pure rec" the implementation of the recursive **Trsm** described in section 3.1. "BLAS" denotes the variant of section 3.2 with optimal threshold. "delayed<sub>t</sub>" denotes the variant of section 3.3 where t satisfies equation 3. In our comparisons we use the fields presented in section 2 as base fields and the version 3.4.2 of ATLAS. Performances are expressed in million of finite field operations (Mfops) per second for  $n \times n$  dense systems.

Table 1: Comparing speed (Mfops) of Trsm using Modular<double>, on a P4, 2.4GHz (Upper table is over  $Z_5$ , lower table is over  $Z_{32749}$ )

One can see from table 1 that the "BLAS" Trsm variant with a Modular<double> representation is the most efficient choice for small primes (here switching to BLAS happens for n = 23 when p = 5 and m = 53). Now for big primes, despite the very small granularity (switching to BLAS happens only for n = 3 when p = 32749 and m = 53), this choice remains the best as soon as the systems are bigger than  $1000 \times 1000$ . This is because grouping operations into blocks speeds up the computation. Now in the case of smaller systems, the "delayed" variant is more efficient, due to the good behavior of dot product. However the threshold t has to be chosen carefully. Indeed using a threshold of 50 enables bet-

Table 2: Comparing speed (Mfops) of Trsm using Givaro-ZpZ, on a P4, 2.4GHz (Upper table is over  $Z_5$ , lower table is over  $Z_{32749}$ )

ter performances than the BLAS variant. This is because the conversion from machine integers to floating point numbers becomes too big a price to pay. As a comparison, we also provide performances for several thresholds, in particular the same as in the BLAS variant (3 and 23). Then for larger matrices, conversions ( $O(n^2)$ ) are dominated by computations ( $O(n^{\omega})$ ), and the "BLAS" variant is again the fastest one, provided that the field is small enough.

Now, table 2 reflects experiments using the integer based modular fields of Givaro, Givaro-ZpZ. First, using these fields, Trsm is slower than with Modular<double>. This is due to the conversions needed for the matrix multiplications. Note that with the shown thresholds (not bigger than 100) the "overflow trick" used for the dotproduct slightly reduces this loss because it also reduces the number of conversions needed for the dotproduct.

To summarize, one would rather use a Modular<double> representation and the "BLAS" Trsm variant in most cases. However, when the base field is already specified, delayed<sub>t</sub> could provide slightly better performances. This requires a search for optimal thresholds which could be done through an Automated Empirical Optimizations of Software[23].

#### 4. TRIANGULARIZATIONS

We now come to the core of this paper, namely the matrix multiplication based algorithms for triangularization over finite fields. The main concern here is the singularity of the matrices. Moreover, practical implementations need to efficiently deal with the rank profile, unbalanced dimensions, memory management, recursive thresholds, etc. Therefore, in this section we present three variants of the recursive exact triangularization. First the classical LSP of Ibarra et al. is sketched. In order to reduce its memory requirements, a first version, LUdivine, stores L in-place, but temporarily uses some extra memory. Our last implementation is fully in-place without any extra memory requirements and corresponds to Ibarra's LQUP. From both LUdivine and LQUP one can easily recover the LSP via some extractions and permutations.

#### 4.1 LSP Factorization

The LSP factorization is a generalization of the well known block LUP factorization for the singular case [1]. Let A be a  $m \times n$  matrix, we want to compute the triple  $\langle L, S, P \rangle$ such that A = LSP. The matrices L and P are as in LUP factorization and S reduces to a non-singular upper triangular matrix when zero rows are deleted. The algorithm with best known complexity computing this factorization uses a divide and conquer approach and reduces to matrix multiplication [16]. Let us describe briefly the behavior of this algorithm. The algorithm is recursive: first, it splits A in

Figure 2: Principle of the LSP factorization

halves and performs a recursive call on the top block. It thus gives the T, Y and  $L_1$  blocks of figure 2. Then, after some permutations ( $[XZ] = [A_{21}A_{22}]P$ ), it computes G such that GT = X via **Trsm**, replaces X by zeroes and eventually updates Z = Z - GY. The third step is a recursive call on Z. We let the readers refer e.g. to [2, (2.7c)] for further details.

LEMMA 4.1. Algorithm LSP is correct. The leading term of its theoretical cost is bounded by  $\frac{C_{\omega}}{2^{\omega-1}-2}m^{\omega-1}\left(n+\frac{m}{2^{\omega}-2}\right)$ arithmetic operations in  $\mathbb{Z}_p$  for  $m \leq n$ .

This refines Ibarra's original factor [16, Theorem 2.1] from 3n to  $n + \frac{m}{2\omega-2}$ . Moreover, when each one of the intermediate block is of full rank, this factor even reduces to  $n - m \frac{2^{\omega-2}-1}{2\omega-1-1}$  [19, Theorem 1]. And this nicely gives  $\frac{2}{3}n^3$ , when  $\omega = 3$ , n = m and  $C_{\omega} = C_3 = 2$ .

The point here is that, L being square  $m \times m$  does not fit in place under S. Therefore a first implementation produces an extra triangular matrix. The following subsections address this memory issue.

### 4.2 LUdivine

The main concern with the direct implementation of the LSP algorithm, is the storage of the matrix L: it can not be stored with its zero columns under S (as shown in figure 2). Actually, there is enough room under S to store all the non zero entries of L, as shown in figure 3. Storing only the non zero columns of L is the goal of the LUdivine variant. One can notice that this operation corresponds to the storage of  $\tilde{L} = LQ$  instead of L, where Q is a permutation matrix such that  $Q^T S$  is upper triangular. Consequently, the recovery of L from the computed  $\tilde{L}$  is straightforward. Note that this  $\tilde{L}$  corresponds to the echelon form of [17, §2] up to some transpositions.

Further developments on this implementation are given in [3, 19]. However, this implementation is still not fully in place. Indeed, to solve the triangular system  $G = X.T^{-1}$ , one has then to convert T to an upper triangular matrix stored in a temporary memory space. In the same way,

Figure 3: Principle of the LUdivine factorization

the matrix product Z = Z - GY also requires a temporary memory allocation, since rows of Y have to be shifted. This motivates the introduction of the LQUP decomposition.

# 4.3 LQUP

To solve the data locality issues, due to zero rows inside S, one can prefer to compute the LQUP factorization, also introduced in [16]. It consists in a slight modification of the LSP factorization: S is replaced by U, the corresponding upper triangular matrix, after the permutation of the zero rows. The transpose of this row permutation is stored in Q.

Figure 4: Principle of the LQUP factorization

This prevents the use of temporaries for Y and T, since the triangles in U are now contiguous. Moreover, the number of instructions to perform the row permutations is lower than the number of instructions to perform the block copies of LUdivine or LSP. Furthermore, our implementation of LQUP also uses the trick of LUdivine, namely storing L in its compressed form  $\tilde{L}$ . Thanks to all these improvements, this triangulation appears to be fully in place. As will be shown in section 4.4, it is also more efficient. Here again, the LSP and LQUP factorizations are simply connected via S = QU. So the recovery of the LSP is still straightforward.

#### 4.4 Comparisons

As shown in previous sections the three variants of triangularization mainly differ by their memory management. Indeed, the main operations remain matrix multiplications and triangular system solving. Therefore, the implementation of all these variants use the fast matrix multiplication routine of the FFLAS package [8] and the triangular system solver of subsection 3.2 as kernel. The results are impressive: for example, table 3 shows that it is possible to triangularize a  $5000 \times 5000$  matrix over a finite field in 29.9 seconds. We now compare the three routine speed and memory usage with the same kernels: a Modular<double> representation (so that no conversion overhead occur) and the recursive

with BLAS Trsm. For table 3, we used random dense square

n	400	1000	3000	5000	8000	10000
LSP	0.05	0.48	8.01	32.54	404.8	1804
LUdivine	0.05	0.47	7.79	30.27	403.9	1691
LQUP	0.05	0.45	7.59	29.90	201.7	1090

Table 3: Comparing real time (seconds) of LSP, LUdivine, LQUP over  $\mathbb{Z}_{101}$ , on a P4, 2.4GHz

matrices (but with 3n non-zero entries) so as to have rank defficient matrices. The timings given in table 3 are close since the dominating operations of the three routines are similar. LSP is slower, since it performs some useless zero matrix multiplications when computing Z = Z - GY (section 4.2). LQUP is slightly faster than LUdivine since row permutations involve less operations than the whole block copy of LUdivine (section 4.3). However these operations do not dominate the cost of the factorization, and they are therefore of little influence on the total timings. This is true until the matrix size induces some swapping, around  $8000 \times 8000$ .

Now for the memory usage, the fully in-place implementation of LQUP saves 20% of memory (table 4) when compared to LUdivine and 55% when compared to LSP. Actually, the memory usage of the original LSP is approximately that of LUdivine augmented by the extra matrix storage (which corresponds exactly to that of LQUP: e.g. 5000 \* 5000 \* 8bytes = 200Mb). This memory reduction

n	400	1000	3000	5000	8000	10000
LSP	2.83	17.85	160.4	444.2	1136	1779
LUdivine	1.60	10.00	89.98	249.9	639.6	999.5
LQUP	1.28	8.01	72.02	200.0	512.1	800.0

Table 4: Comparing memory usage (Mega bytes) of LSP, LUdivine, LQUP over  $\mathbb{Z}_{101}$ , on a P4, 2.4GHz with 512 Mb RAM

is of high interest when dealing with large matrices (further improvements on the memory management are presented section 4.5).

#### 4.5 Data locality

To solve even bigger problems, say that the matrices do not fit in RAM, one has mainly two solutions: either perform out of core computations or parallelize the resolution. In both cases, the memory requirements of the algorithms to be used will become the main concern. This is because the memory accesses (either on hard disk or remotely via a network) dominate the computational cost. A classical solution is then to improve data locality so as to reduce the volume of these remote accesses. In such critical situations, one may have to prefer a slower algorithm having a good memory management, rather than the fastest one, but suffering from high memory requirements. We here propose to deal with this concern in the case of rank or determinant computations of large dense matrices. The generalization to the full factorization case being direct but not yet fully implemented.

To improve data locality and reduce the swapping, the idea is to use square recursive blocked data formats [13]. A

variation of the LSP algorithm, namely the TURBO algorithm [9], adapts this idea to the exact case. Alike the LQUP algorithm which is based on a recursive splitting of the row dimension (see section 4.3), TURBO achieves more data locality by splitting both row and column dimensions. Indeed the recursive splitting with only the row dimension tend to produce "very rectangular" blocks: a large column dimension and a small row dimension. On the contrary, TURBO preserves the squareness of the original matrix for the first levels. More precisely each recursive level consists in a splitting of the matrix into four static blocks followed by five recursive calls to matrix triangularizations (U, V, C, D, and Z, in that order on figure 5), six Trsm and four matrix multiplications for the block updates. In this first implementation,

Figure 5: Principle of the TURBO decomposition

only one recursive step of TURBO is used, the five recursive calls being performed by the LQUP algorithm. For the actual size of matrices, the quite complex implementation of more recursive levels of TURBO is not yet mandatory.

Now for the comparisons of figure 6, we use the full LQUP factorization algorithm as a reference. Factorization of matrices of size below 8000 fit in 512Mb of RAM. Then LQUP is slightly faster than TURBO, implementation of the latter producing slightly more scattered groups. Now, the first field representation chosen (curves 1 and 2) is a modular prime field representation using machine integers. As presented in [8], any matrix multiplication occurring in the decomposition over such a representation is performed by converting the three operands to three extra floating point matrices. This memory overhead is critical in our comparison. TURBO, having a better data locality and using square blocks whenever possible, requires smaller temporary matrices than the large and very rectangular blocks used in LQUP. Therefore, for matrices of order over 8000, LQUP has to swap a lot while TURBO remains more in RAM. This is strikingly true for matrices between 8000 and 8500, where TURBO manages to keep its top speed.

Moreover, one can also reduce the memory overhead due to the conversions to floating point numbers, by using the modular<double> field representation, as described in section 2. There absolutely no allocation is done beside the initial matrix storage. On the one hand, performances increase since the conversions and copy are no longer performed, as long as the computations remain in RAM (see curves 3 and 4). On the other hand, the memory complexities of both algorithms now become identical. Furthermore, this fully inplace implementation does not create small block copies any-

Figure 6: TURBO versus LQUP for out of core rank

more. Paradoxically, this prevents the virtual blocks from fitting in the RAM, since they are just a view of the large initial matrix. For this reason, both performance losses appear for matrices of order around 8000. However, the drop is lower for TURBO thanks to the recursive blocked data formats producing better data locality.

This behavior of course confirms that as soon as the RAM is full, data locality becomes more important than memory saves : TURBO over Givaro-Zpz is the fastest for matrices of size bigger than 8000, despite its bigger memory demand. This is advocating further uses of recursive blocked data formats and of more recursive levels of TURBO.

# 5. RANK, DETERMINANT, INVERSE

The LQUP factorization and the Trsm routines reduce to matrix multiplication as we have seen in the previous sections. Theoretically, as matrix multiplication requires  $2n^3 - n^2$  arithmetic operations, the factorization, requiring at most  $\frac{2}{3}n^3$  arithmetic operations, could be computed in about  $\frac{1}{3}$  of the time. Now, the matrix multiplication routine Fgemm of FFLAS package can compute  $5000 \times 5000$  matrix multiplications in only 56.43 seconds on a 2.4GHz pentium 4. This is achieved with pipelining within the P4 processor and with very good performances of the BLAS. This corresponds to 4430 millions of finite field arithmetic operations per seconds! Well, table 5 shows that with  $n \times n$  matrices we are not very far from these quasi-optimal performances also for the factorization:

n	400	700	1000	2000	3000	5000
LQUP	0.05s	0.19s	0.45s	2.58s	7.59s	29.9s
Fgemm	0.05s	0.24s	0.66s	4.49s	12.66s	56.43s
Ratio	1	0.78	0.68	0.57	0.6	0.53

Table 5: Comparing cpu time of Matrix Multiplication and Factorization over  $\mathbb{Z}_{101}$ , on a P4, 2.4GHz

Moreover, from the two routines, one can also easily derive several other algorithms:

• The **rank** is the number of non-zero rows in U.

• The **determinant** is the product of the diagonal elements of U (stopping whenever a zero is encountered).

• The **inverse** is also straightforward:

Algorithm Inverse(A) Input:  $A \in \mathbb{Z}_p^{m \times m}$ , non singular. Output:  $A^{-1} \in \mathbb{Z}_p^{m \times m}$ . Scheme L, U, P := LQUP(A). (A is invertible, so  $Q = I_m$ ) X := LLeft-Trsm(L, Id).  $A^{-1} := P^T$  ULeft-Trsm(U, X).

Now, the inverse can then be computed with at most  $\frac{2}{3}n^3 + 2n^3$  arithmetic operations which gives a theoretical ratio of  $\frac{4}{3}$ . Once again, table 6 proves that our implementation has pretty good performances: Indeed, operations per-

n	400	700	1000	2000	3000	5000
Inv	0.2s	0.76s	1.9s	11.27s	32.08s	132.72s
Fgemm	0.05s	0.24s	0.66s	4.49s	12.66s	56.43s
Ratio	4	3.17	2.92	2.51	2.53	2.35

#### Table 6: Comparing cpu time of Matrix Multiplication and Inverse over $\mathbb{Z}_{101}$ , on a P4, 2.4GHz

formed in LQUP, or Trsm are not grouped as well as in Fgemm. Therefore, the excellent performances of Fgemm make the ratio somewhat unreachable, although the invert routine is very fast. Note that, as the first LLeft-Trsm call is made on the identity it could be accelerated in a specific routine. Indeed, during the course of LUP,  $L^{-1}$  can actually be computed with only a  $\frac{n^3}{3}$  overhead, thus reducing the theoretical ratio from 4/3 to 1.

# 6. CONCLUSIONS

We have achieved the goal of approaching the speed of the numerical factorization of any shape and any rank matrices, but for finite fields. For example, the LQUP factorization of a  $3000 \times 3000$  matrix over a finite field takes 7.59 seconds where 6 seconds are needed for the numerical LUP factorization of  $lapack^6$ . To reach these performances one could use blocks that fit the cache dimensions of a specific machine. In [8] we proved that this was not mandatory for matrix multiplication. We think we prove here that this is not mandatory for any dense linear algebra routine. By the use of recursive block algorithms and efficient numerical BLAS, one can approach the numerical performances. Moreover, long range efficiency and portability are warranted as opposed to every day tuning with at most 10% loss for large matrices (see table 2 where delayed can beat BLAS only for big primes and with a specific empirical threshold).

Besides, the exact equivalent of stability constraints for numerical computations is coefficient growth. Therefore, whenever possible, we computed and improved theoretical bounds on this growth (see bounds 3.3 and [8, Theorem 3.1]). Those optimal bounds enable further uses of the BLAS routines.

Further developments include:

• A Self-adapting Software [5] (to switch to different algorithms during the recursive course of **Trsm** and **TURBO**), could be used to find the best empirical thresholds.

• The other case where our wrapping of BLAS is insufficient is for very small matrices (see tables 1 and 2). Here also, automated tuning would produce improved versions.

• The extension of the factorization to some other algorithms as shown for the Inverse (e.g. null-space computation as in [4]) is in progress.

• Finally, extending the out of core work of section 4.5 to design a parallel library is promising.

# APPENDIX

# A. PROOF OF THEOREM 3.2

THEOREM 3.2 Let  $T \in \mathbb{Z}^{n \times n}$  be a unit diagonal upper triangular matrix, and  $b \in \mathbb{Z}^n$ , with  $|T| \leq p-1$  and  $|b| \leq p-1$ . Let  $X = (x_i)_{i \in [1..n]} \in \mathbb{Z}^n$  be the solution of T.X = bover the integers.

Then

$$\forall k \in [0..n-1] \begin{cases} -u_k \le x_{n-k} \le v_k & \text{if } k \text{ is even} \\ -v_k \le x_{n-k} \le u_k & \text{if } k \text{ is odd} \end{cases}$$
(4)

where

$$\begin{cases} u_n = \frac{p-1}{2} \left[ p^n - (p-2)^n \right] \\ v_n = \frac{p-1}{2} \left[ p^n + (p-2)^n \right] \end{cases}$$

PROOF. Let us define the induction hypothesis  $IH_l$  to be that the equations (4) are true for  $k \in [0..l-1]$ .

When l = 0,  $x_n = b_n$  which implies that  $-u_0 = 0 \le x_n \le p - 1 = v_0$ . Thus  $IH_0$  is proven.

Let us suppose that  $\forall j \in [0.l] \ IH_j$  is true, and prove  $IH_{l+1}$ . There are two cases: either l is odd or not !

If l is odd, l+1 is even. Now, by induction, an upper bound for  $x_{n-l-1}$  is

$$(p-1)\left(1+\sum_{i=0}^{\frac{l-1}{2}}u_{2i}+v_{2i+1}\right)$$

$$\leq p-1+\sum_{i=0}^{\frac{l-1}{2}}\frac{(p-1)^2}{2}\left[p^{2i}-(p-2)^{2i}+p^{2i+1}+(p-2)^{2i+1}\right]$$

$$\leq p-1+\sum_{i=0}^{\frac{l-1}{2}}\frac{(p-1)^2}{2}\left[p^{2i}(p+1)+(p-2)^{2i}(p-3)\right]$$

$$\leq p-1+\frac{(p-1)^2}{2}\left[(p+1)\frac{p^{l+1}-1}{p^2-1}+(p-3)\frac{(p-2)^{l+1}-1}{(p-2)^2-1}\right]$$

$$\leq \frac{p-1}{2}\left[p^{l+1}+(p-2)^{l+1}\right]$$

$$\leq v_{l+1}$$

Similarly, a lower bound for  $x_{n-l-1}$  is

$$\begin{aligned} &-(p-1)\sum_{i=0}^{\frac{l-1}{2}} v_{2i} + u_{2i+1} \\ &\geq \quad -\frac{(p-1)^2}{2}\sum_{i=0}^{\frac{l-1}{2}} \left[ p^{2i} + (p-2)^{2i} + p^{2i+1} - (p-2)^{2i+1} \right] \\ &\geq \quad -\frac{(p-1)^2}{2}\sum_{i=0}^{\frac{l-1}{2}} \left[ p^{2i}(p+1) - (p-2)^{2i}(p-3) \right] \\ &\geq \quad -\frac{p-1}{2} \left[ p^{l+1} - (p-2)^{l+1} \right] \\ &\geq \quad -u_{l+1} \end{aligned}$$

Finally, If l is even, a similar proof leads to

$$-v_{l+1} \le x_{n-l+1} \le u_{l+1}$$
